

IN THE SPECIFICATION:

Please replace the abstract with the following amended abstract:

In a signal processing device which performs data compression, a thinning circuit **1** generates thinned data by thinning input PCM data. For example, when a sampling rate f_s of the PCM data (original data) is $f_s = 10$ Hz, thinned data of $f_s = 1$ Hz is generated. The determination circuit **2** controls the selection circuit **4** so that, based on the following expression: $TOTAL1 = |X(n) - X(n-1)| + |X(n-1) - X(n-2)| + \dots + |X(n-8) - X(n-9)|$, if $TOTAL1 > C1$, the input PCM data is selected, and if otherwise the thinned data is selected. The selected data and the determination result information of the determination circuit **2** are written into a memory **3**. Therefore, data compression is performed with respect to original data with a simple circuit configuration and without losing required information of the original data.
